## Abstract

The stock abundance and biomass increased from 23 million individuals and 45 000 tons in 1984 to 828 million individuals and 690 000 tons in 1987 due to the recruitment of the predominating year classes 1984 and 1985. Since 1988, stock abundance and biomass decreased dramatically by 99 % to 5 million individuals and 6 000 tons in 1993. The 2001 estimates confirmed the severely depleted status of the stock. However, the 2001 estimates confirmed the severely depleted status of the stock, although they represent the highest stock size since 10 years. The total abundance and biomass indices amounted to 16 million individuals and 18 000 tons, respectively.

48 % of the stock in number was distributed off East Greenland with a more diverse age structure than off West Greenland. The recruiting year classes 1998, 1999 and 2000 are considered weak as compared to the strong 1984 and 1985 year classes. The year class 1999 at age 2 however is estimated as the third strongest year class since 1982 and thus to provide some recovery potential in the next few years. The O-group indices are considered unrepresentative of year class strength at age 3 due to gear specifications while the age group 1 seems to be quantitatively estimated and to represent a reasonable recruitment index.

Since 1997, the cod did mature at significantly lower ages, probably as a reaction to the continued favourable water temperature in the near bottom layers. The weighted mean length and weight of the age groups 3-6 revealed pronounced area and temperature effects. Driven by the high abundance of cod off West Greenland, the mean sizes of the age groups 1-6 were low in 1987-91. The mean length and weight of age groups 3-6 increased significantly from low levels since 1991 as a consequence of their increased occurrence off East Greenland and higher temperatures.

## Introduction

This paper presents estimates of cod stock abundance and biomass indices disaggregated by age groups as derived from annual groundfish surveys commenced in 1982, the only regular source of quantitative information from the traditional fishing grounds off West and East Greenland south of 67° northern latitude. Size at age is given in terms of length and weight. Changes in size at age are analysed for area and temperature effects.

## Materials and Methods

Abundance, biomass estimates and length structures were derived from annual groundfish surveys covering shelf areas and the continental slope off West and East Greenland. Surveys commenced in 1982 and were primarily designed for the assessment of cod. Because of favourable weather and ice conditions and to avoid spawning concentrations, autumn was chosen for the time of the surveys. These were carried out by the research vessel (R/V) WALTHER HERWIG (II) throughout most of the time period. In 1984 R/V ANTON DOHRN was used and she was replaced by the new R/V WALTHER HERWIG III since 1994, respectively.

The fishing gear used was a standardized 140-feet bottom trawl, its net frame rigged with heavy ground gear because of the rough nature of the fishing grounds. A small mesh liner (10mm) was used inside the cod end. The horizontal distance between wing-ends was 25 m at 300 m depth, the vertical net opening being 4 m. In 1994, smaller Polyvalent doors ( $4.5 \text{ m}^2$ , 1,500 kg) were used for the first time to reduce net damages due to overspread caused by bigger doors ( $6 \text{ m}^2$ , 1,700 kg), which have been used earlier. All calculations of abundance and biomass indices were based on the 'swept area' method using 22 m horizontal net opening as trawl parameter, i. e. the constructional width specified by the manufacturer. The towing time was normally 30 min. at a speed of 4.5 knots. Trawl parameters are listed in Table 1. Hauls, which received net damage or became hang-up after less than 15 minutes, were rejected. Some hauls of the 1987 and 1988 surveys were also included although their towing time had been intentionally reduced to 10 minutes because of the expected large cod catches as observed from echo sounder traces.

Fish were identified to species or lowest taxonomic level and the catch in number and weight was recorded. Total fish lengths were measured to cm below. Weight (g) at age calculations were based on the regression  $f(x)=0.00895x^{3.00589}$ ,  $x=\text{length (cm)}$ , which was determined on the basis of 3 482 individual measurements.

The surveys were primarily designed for the assessment of cod. In order to reduce the error of abundance estimates, the subdivision of shelf areas and the continental slope into different geographic and depth strata was required due to a pronounced heterogeneity of cod distribution. The survey area was thus split into seven geographic strata. Each stratum was itself subdivided into two depth strata covering the 0-200 m and 201-400 m zones. Figure 1 and Table 2 indicate the names of the 14 strata, their geographic boundaries, depth ranges and areas in nautical square miles ( $\text{nm}^2$ ). All strata were limited at the 3 mile offshore line.

The applied strategy was to distribute the sampling effort according both to the stratum areas and to cod abundance. Consequently, fifty percent of the hauls were allocated proportionally to strata by stratum area while the other fifty percent were apportioned on the basis of a review of the historical mean cod abundance/ $\text{nm}^2$ , all hauls being randomly distributed within trawlable areas of the various strata. Non-trawlable areas were mainly located inshore. During 1982-2001, 2 854 successful sets were carried out, the numbers of valid sets by year and stratum being listed in Table 3. Apart from stratum 7.2 (Dohrn Bank), East Greenland strata were not covered adequately in 1984, 1992 and 1994 due to technical problems. In 1995, the survey area off West Greenland was incompletely covered for the first time again due to technical problems. Only 50 % of the strata of West Greenland were covered, namely the southern strata 3.1, 3.2, 4.1, and 4.2. Stratum 7.1 has a very low area and therefore never been covered. Since 1996, the survey area was covered almost completely. Figure 1 shows the positions of hauls conducted during the most recent survey.

Stratified abundance estimates were calculated from catch-per-tow data using the stratum areas as weighting factor (Cochran, 1953; Saville, 1977). Strata with less than five valid sets were rejected from the calculation. The coefficient of catchability was set arbitrarily at 1.0, implying that estimates are merely indices of abundance and biomass. Respective confidence intervals (CI) were set at the 95% level of significance of the stratified mean.

Age determinations were based on length-stratified otolith (sagitta) collections and conducted using transmitted light. Until 1992, otoliths were cut into 2 halves and annuli were counted under a binocular microscope. Since 1993, thin sections were cut from the central region of the otolith after embedding in black polyester resin.

Comparative age readings revealed no significant differences between both methods. Calculations of age structures, compositions and growth were based on data pooled to 3 cm length groups. In 2001, 1 242 individual age determinations were available.

Maturity at age was determined from visual observations. However, the results should be interpreted carefully since the surveys were conducted in autumn when the gonads were in resting stages. During this season, it was often difficult to distinguish immature from mature cod.

As a standard procedure, near bottom temperatures were measured directly before or after trawling in the vicinity of the swept area by a CTD-sonde with a precision of a hundredth °C. Mean weighted temperature in the near bottom layer was calculated using the stratum areas as weighting factor. The values are given in Table 3.

## Results

Tables 4 and 5 list abundance and biomass indices by stratum, West and East Greenland and total in 1982-2001. Indices varied significantly between strata and years. Trends of the abundance and biomass estimates for West and East Greenland are shown in Figures 2 and 3, respectively. These Figures illustrate the pronounced increase in stock abundance and biomass from 23 million individuals and 45 000 tons in 1984 to 828 million individuals and 690 000 tons in 1987. This trend was caused by the recruitment of the predominating year classes 1984 and 1985, which were mainly distributed in the northern and shallow strata 1.1, 2.1 and 3.1 off West Greenland during 1987-89. Such high indices were never observed in strata off East Greenland, although their abundance and biomass estimates increased during the period 1989-91 pointing to eastbound migration. During the period 1987-89, the high abundance estimates were accompanied with high confidence intervals. The low precisions were due to enormous variation in catch per tow data. Since 1988, stock abundance and biomass decreased dramatically by 99 % to 5 million individuals and 6 000 tons in 1993. However, the 2001 estimates confirmed the severely depleted status of the stock, although they represent the highest stock size since 10 years. The total abundance and biomass indices amounted to 16 million individuals and 18 000 tons, respectively.

Age disaggregated abundance indices for West, East Greenland and total are listed in Tables 6, 7 and 8, respectively. The very strong year classes 1984 and 1985 dominated the stock during 1985-1991. In 2001, the stock structure off West Greenland was found to be composed almost exclusively of the recruiting age groups 1, 2 and 3 (97 %). 48 % of the stock in number was distributed off East Greenland with a more diverse age structure. As the abundance indices of the fully recruited age groups 4 and 5 increased from 2000 to 2001, the higher stock abundance estimate is subject to a small year effect in catchability (overestimation). The recruiting year classes 1998, 1999 and 2000 are considered weak as compared to the strong 1984 and 1985 year classes. The year class 1999 at age 2 however is estimated as the third strongest year class since 1982 and thus to provide some recovery potential in the next few years. The O-group indices are considered unrepresentative of year class strength at age 3 due to gear specifications while the age group 1 seems to be quantitatively estimated and to represent a reasonable recruitment index (Fig. 4).

The proportion mature at age and resulting estimates of spawning stock sizes in numbers and weight are given in Tables 9, 10 and 11, respectively. The calculation of the spawning stock biomass indices were based on the weighted mean weight by age and years as listed in Tables 15-17. In the past four years, the cod did mature at significantly lower ages, probably as a reaction to the continued favourable water temperature in the near bottom layers (Rätz, 1999). The indices of spawning stock sizes are illustrated in Figures 2 and 3 as solid lines. Both estimates peaked in 1989 when the strong year class 1984 became mature. In recent years, the spawning stock was practically absent.

The weighted mean length and weight of the age groups 1-10 years for West, East Greenland and total are listed in Tables 12-17, respectively. Trends of these values are illustrated in Figures 5 and 6 for the period 1982-2001. They reveal pronounced area and temperature effects as demonstrated by multiple linear regression models (Fig. 7 and Tab. 18). 38, 57, 62, and 39 % of the observed variation in length at ages 3-6 are explained by the positive influence of the near bottom temperature and the ratio of fish distributed off East Greenland, respectively. The majority of recorded sizes at ages 2 to 10 years off East Greenland were found to be bigger than those off West Greenland. Driven by the high abundance of small growing cod off West Greenland, the mean sizes of the age groups 1-6 were low in 1987-91. Thereafter, mean length and weight of age groups 3-6 increased significantly from low levels as a consequence of their increased occurrence off East Greenland and higher temperatures.

Table 18 *G. morhua*, Greenland. Linear multiple regression analyses for length at ages 3-6.

dependent variable  $f(x,y)$  = length at age (cm)

independent variable  $x$  = temperature ( $^{\circ}$ C)

independent variable  $y$  = ration of fish distributed off East Greenland

Age Group	function	n	$r^2$
3	$f(x,y)=25.140+3.610x+0.869y$	19	0.38
4	$f(x,y)=35.676+2.814x+7.697y$	19	0.57
5	$f(x,y)=47.690+1.260x+12.643y$	19	0.62
6	$f(x,y)=54.925+1.603x+9.560y$	19	0.39

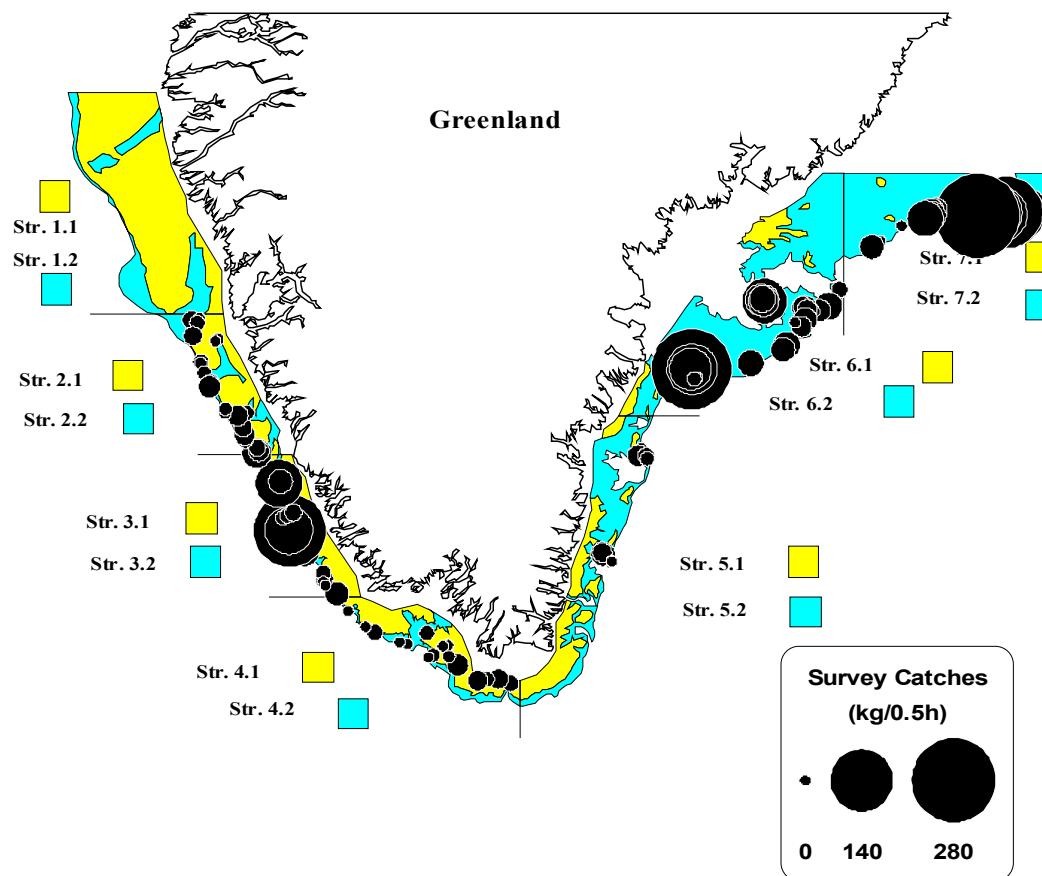

Fig. 1 Stratification of the survey area as specified in Table 2, positions of hauls carried out in 2001 and catches of cod.

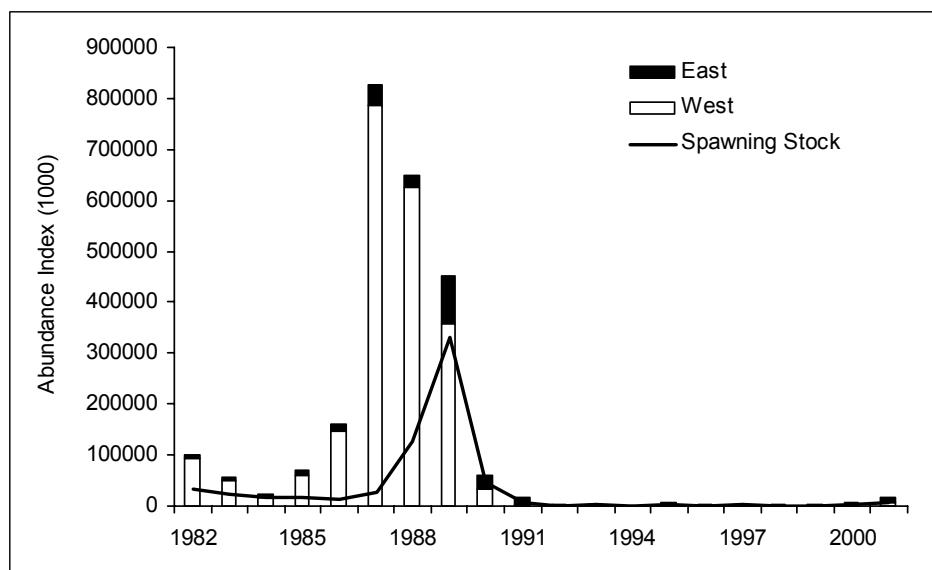

Fig. 2 *G. morhua*. Aggregated survey abundance indices for West and East Greenland and spawning stock size as listed in Tables 4 and 10, 1982-2001. \*) incomplete survey coverage.

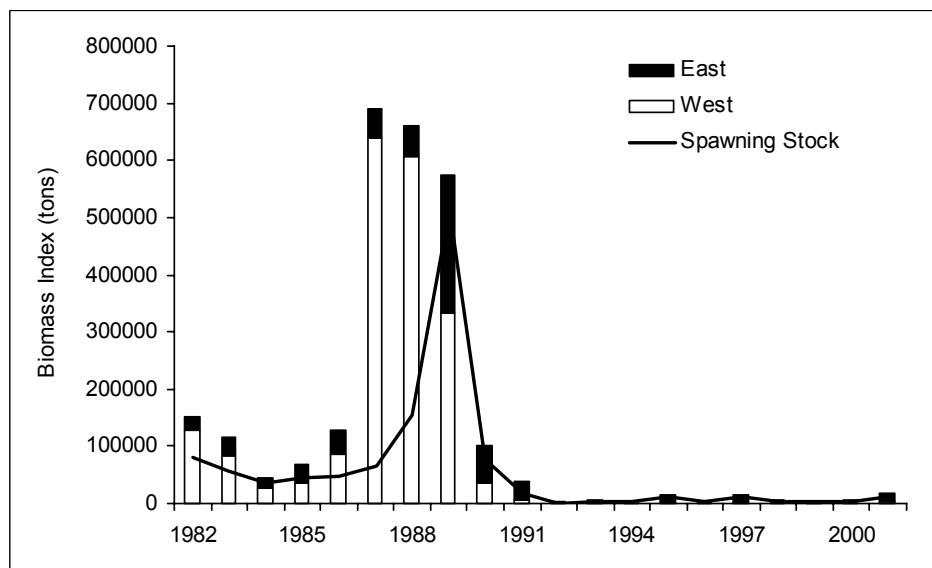

Fig. 3 *G. morhua*. Aggregated survey biomass indices for West and East Greenland and spawning stock size as listed in Tables 5 and 11, 1982-2001. \*) incomplete survey coverage.

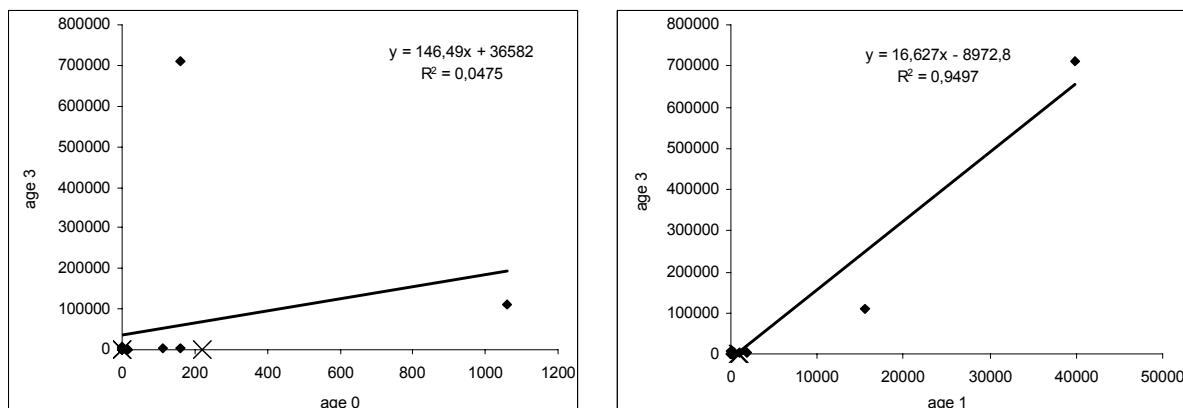

Fig. 4 *G. morhua*. Use of 0 and 1 age group indices to predict year class strength at age 3. The x indicate the 1999, 2000 and 2001 year classes at age 0 and the 1999 and 2000 at age 1, respectively. Values are listed in Table 8.

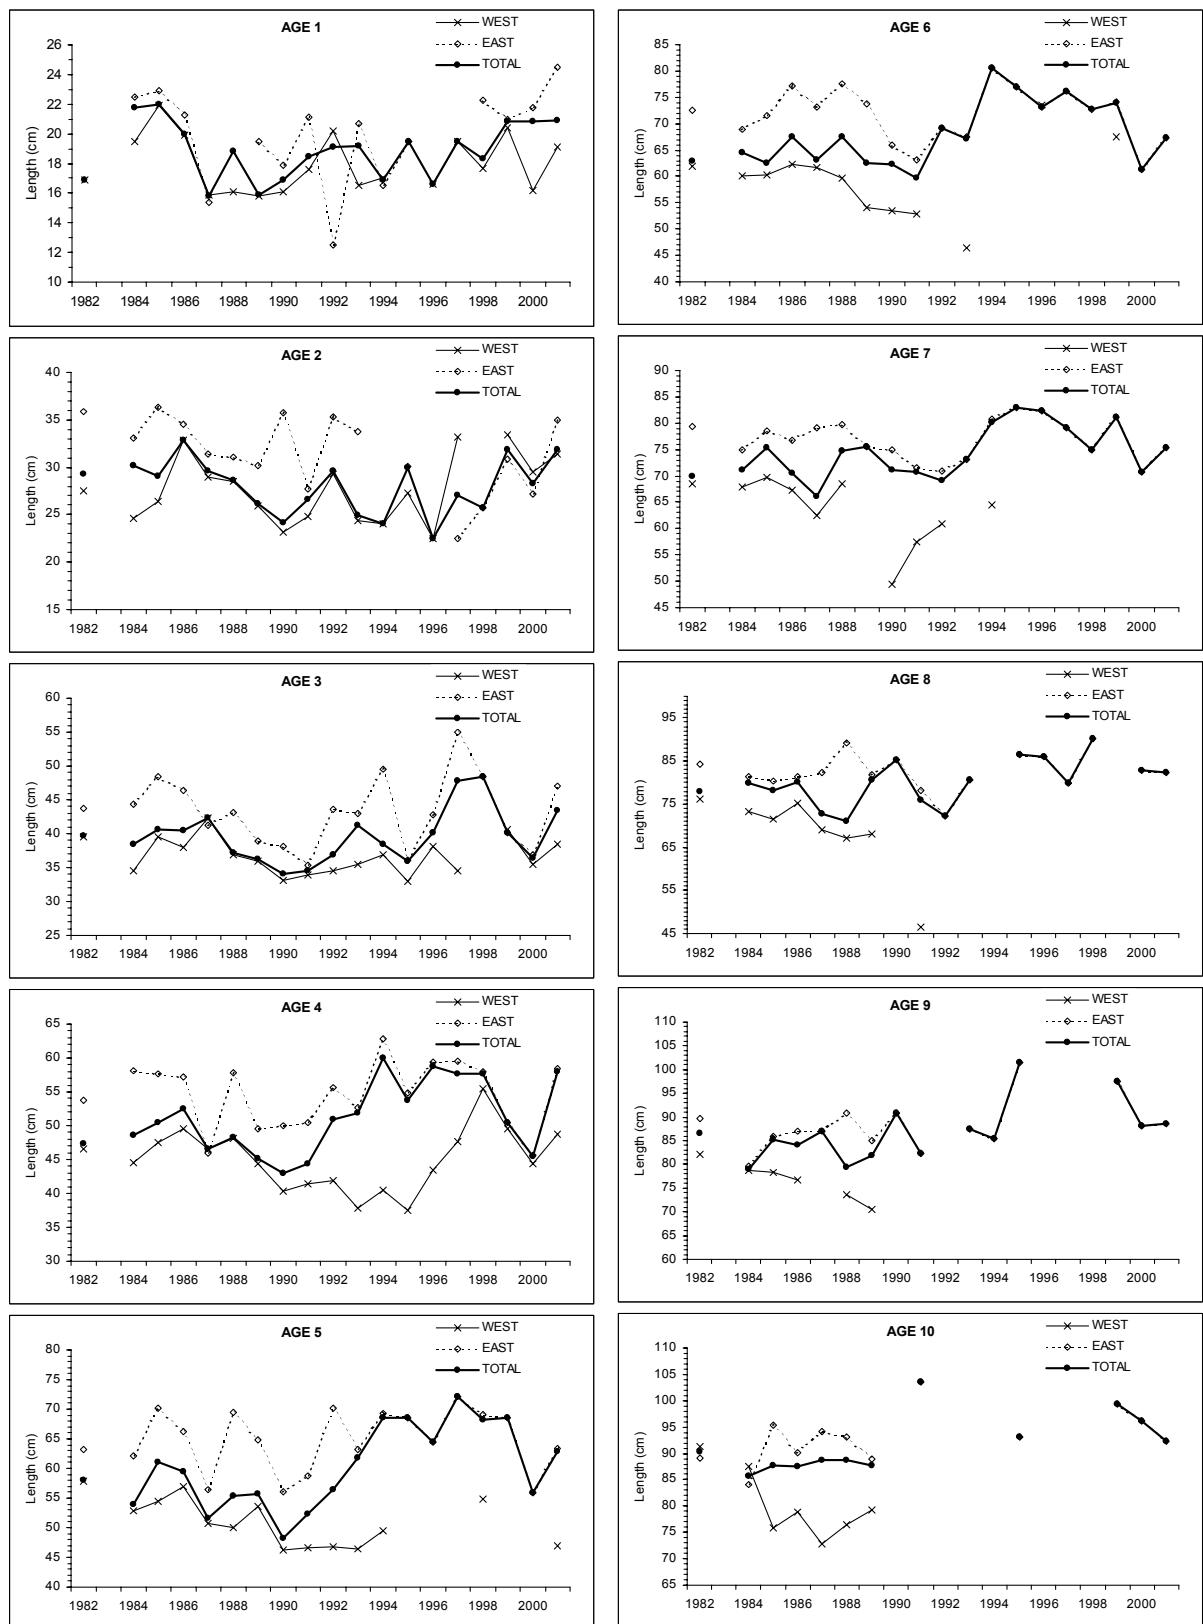

Fig. 5 *G. morhua*. Weighted mean length at age 1-10 years for West, East Greenland and total as listed in Tables 12-14, 1982-2001.

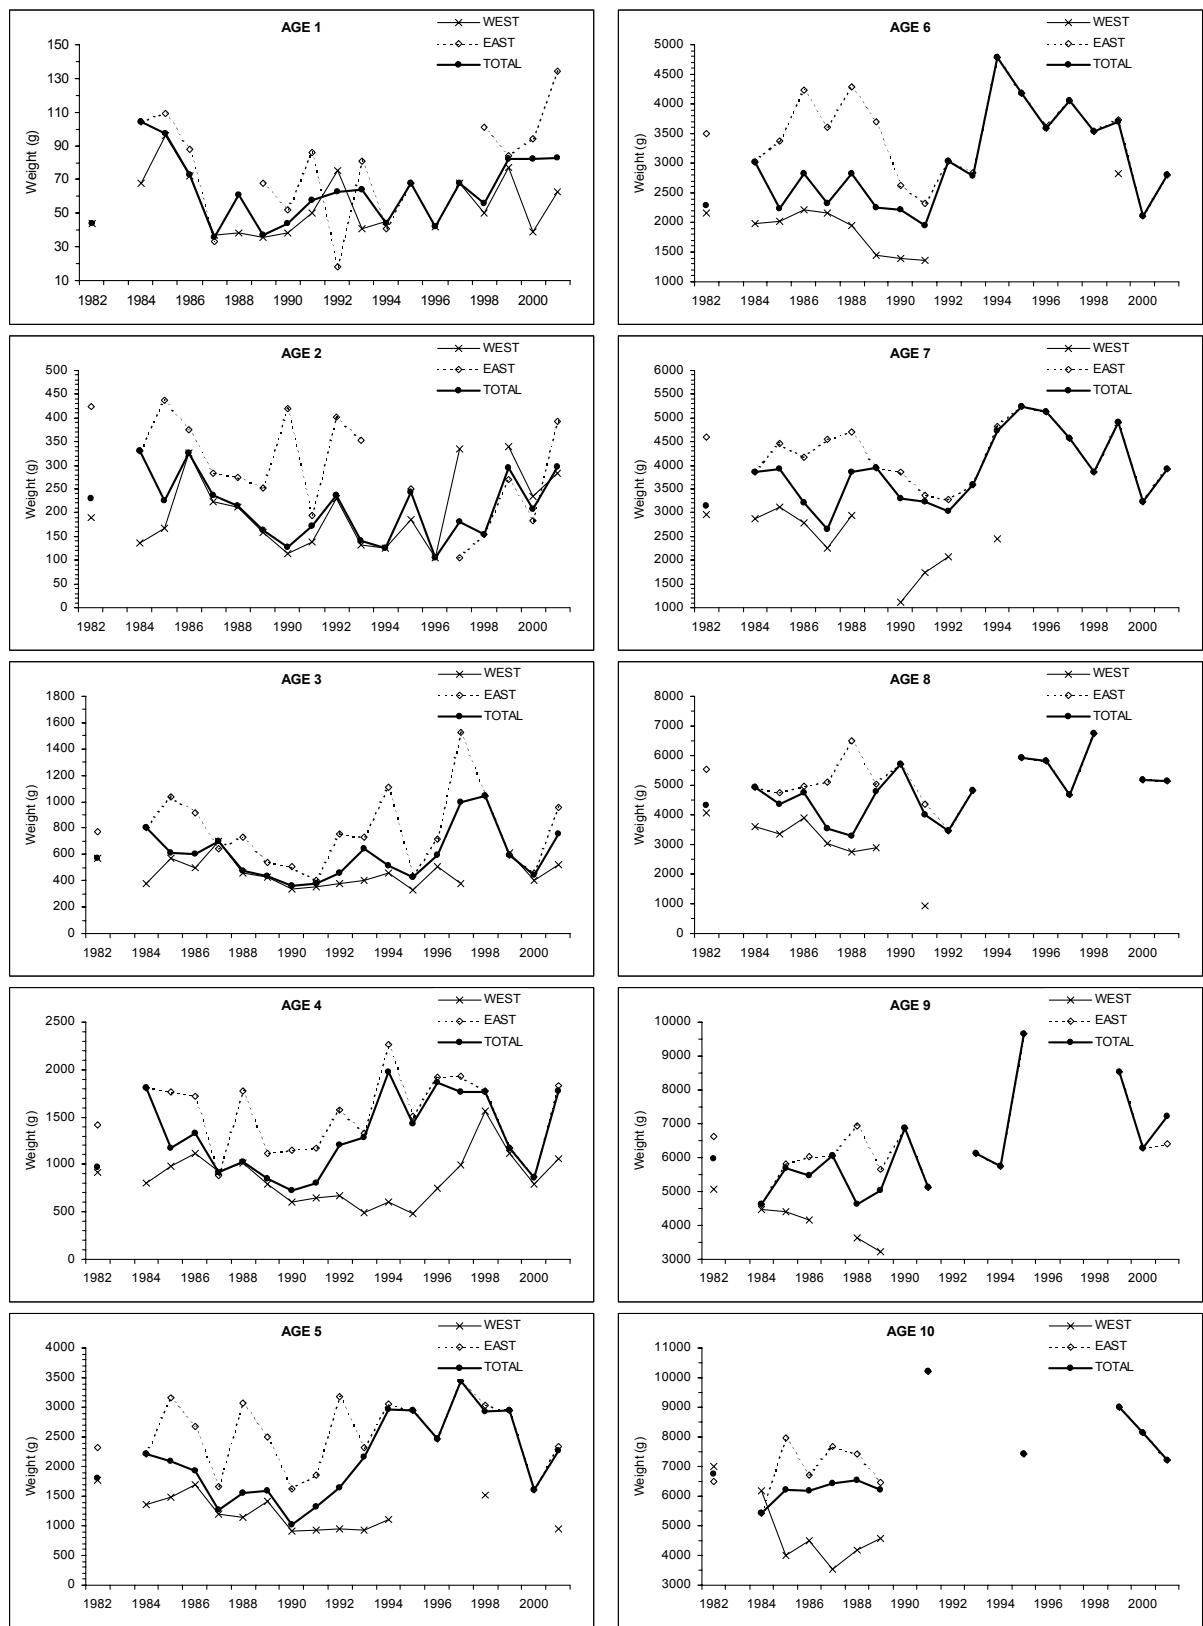

Fig. 6 *G. morhua*. Weighted mean weight at age 1-10 years for West, East Greenland and total as listed in Tables 15-17, 1982-2001.

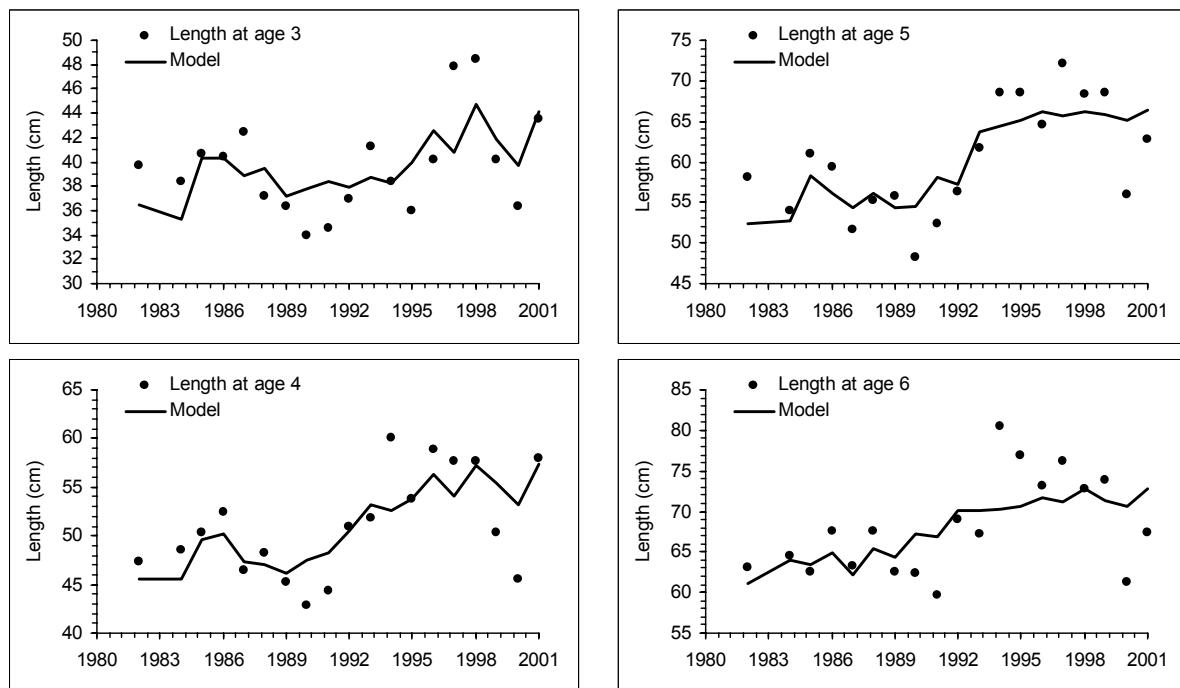

Fig. 7 *G. morhua*, Greenland. Multiple linear regression models for length at ages 3-6 based on near bottom temperature and the ratio of fish distributed off East Greenland. The models are specified in Table 18.
