C.M.1990/Assess:3

REPORT OF THE BLUE WHITING ASSESSMENT WORKING GROUP

Copenhagen, 13-19 September 1989

This document is a report of a Working Group of the International Council for the Exploration of the Sea and does not necessarily represent the views of the Council. Therefore, it should not be quoted without consultation with the General Secretary.

1 INTRODUCTION

1.1 Terms of Reference

The Blue Whiting Assessment Working Group (Chairman: Mr T. Monstad) met at ICES Headquarters from 13 to 19 September 1989 (C.Res.1988/2:4:22) to:

a) assess the status of and provide catch options for 1990 within safe biological limits for the northern and southern blue whiting stock;

b) update the information on the zonal distribution of the stock and the fisheries on the northern blue whiting stock;

c) reevaluate the basis for separate northern and southern stock.

In addition to this, the Working Group was asked by the Chairman of the ACFM to give information for NEAFC on the stock distribution by national zones at other times of the year than the summer period. Furthermore to include in the report any new information in quantitative terms on spatial and temporal distribution of the northern stock.

1.2 Participants

S. Belikov	USSR
L. Danke	German Democratic Republic
O. Gullaksen	Norway
J.A. Jakobsen	Faroe Islands
M. Meixide	Spain
T. Monstad (Chairman)	Norway
A. Paciorkowski	Poland
S. Sveinbjornsson	Iceland
M.E. Vasconcelos	Portugal

2 STOCK IDENTITY AND STOCK SEPARATION

Material from the Fourth Soviet-Norwegian Symposium in June 1989 on Herring and Blue Whiting in the North-East Atlantic was used at the present Working Group meeting (Bakanev, 1989; Belikov et al., 1989b,c; Karasev, 1989; Monstad, 1989a,b; Shevchenko et al., 1989).

The blue whiting in the North-east Atlantic is suggested by many authors to consist of several populations (Anon., 1980, 1981, 1982). The Working Group has assumed, for assessment purposes, two main compononents, i.e., a northern and a southern stock.

The northern stock is known to feed in the Norwegian Sea and spawn west of the British Isles along the slope south to the Porcupine Bank. Nursery areas are in the North Sea with an extension northwards along the Norwegian coast and in the southern part of the Norwegian Sea in Faroese and Icelandic waters (Anon., 1986).

The southern stock is known to have its nursery area on the Continental Shelf off Spain and Portugal where some spawning also takes place. The main spawning of this stock could be along the slope further north towards the Porcupine Bank, and on the bank. The main feeding area, however, is not yet fully known. It could be in the area west and southwest of the Porcupine Bank, where blue whiting have in some years been observed over-wintering (Zilanov, 1984).

The Porcupine Bank area has been considered as a transition area between the two main stocks but may also be inhabited by local populations from the Celtic Sea area.

The basis for separating the blue whiting in the North-East Atlantic into two stocks was reevaluated (as asked in the Terms of Reference). The conclusion was that there is no justification at present to change the assessment units. However, the Working Group is aware of the fact that some of the parameters like the length at maturity (L_{50}) are very sensitive to extrinsic factors, and tend to characterize the environment occupied by the stock as well as the stock itself (Anon., 1983).

Based on biological samples during the acoustic spawning surveys, the USSR in 1986 assigned a part of the biomass in the Porcupine Bank area to the southern stock, and Norway did the same in 1987 (Anon., 1987, 1988). In 1988, however, neither of the two countries was able to do a similar separation in that area (Anon., 1989). Using the method of parasitological indicators, Karasov (1988, 1989) also suggested that the blue whiting at the Porcupine Bank belonged to the northern stock.

The results of a USSR acoustic survey in spring 1989 to the west and northwest of the British Isles, however, suggested that the northern stock of blue whiting consists of two populations. According to the areas where they spawn, these were named the Porcupine and Hebrides stocks (Isaev and Seliverstov, 1989).

The most important index characterizing reproductive capacity of the stock is the population fecundity (PF). Having analysed the conditions of the habitat, PF and stock size of the same year classes, Belikov et al., 1989 concluded that under average survival conditions, for strong year classes to be produced the PF should correspond to a spawning stock of 3.5 million t. A critical level of the PF at which only under extremely favourable survival conditions a strong year class may be expected is 2.0 million t. At lower stock sizes, production of a strong year class is impossible.

The minimum allowable PF was calculated for a single northern stock of blue whiting; that is why under intensive exploitation - if this stock actually consists of two relatively independent entities - one of these can be underexploited, whereas the other can be depleted. If the state of the Porcupine population is not depleted, the Hebrides population is most probably in a critical state due to overexploitation of this stock.

The suggestion by Isaev and Seliverstov to have the northern stock divided in two may well be extended to suggest that the

Porcupine population might also be included in the southern stock. If it is so, the majority of the blue whiting spawning in the Porcupine area belongs to the southern stock, while up to present it has been considered as part of the northern stock.

The Working Group would like to have this matter further discussed in ICES fora and recommends that further investigations be undertaken before any new decision about it is made.

3 OTOLITH EXCHANGE PROGRAMME

An attempt to solve the problem of ageing by finding objective criteria of age determination other than otolith ring counting was initiated during the preceding Working Group meeting (Anon., 1988), and undertaken by T. Linkowski. He tried to fit the multiple regression to the age data as dependent variable against fish length, fish weight, otolith length, otolith height, and otolith weight as independent variables. The resulting correlation coefficients were high, ranging for males from 0.82(R) (all age groups) to 0.93 (age groups 0-7), but the standard error of the estimated age was 1.8 and 0.6 years, respectively. Confidence limits for the model parameters did not allow the prediction of age for older age groups with the required precision (T. Linkowski, pers. comm.). It is expected that more detailed results of the analysis will be presented to the Working Group in 1990.

It was recommended at the last meeting of the Blue Whiting Assessment Working Group to have an otolith exchange between the southern and the northern areas. A set of 115 whole otoliths and corresponding sections was exchanged, as well as photographs of the two series. Results are only available from 3 countries, and the consequent analysis was presented (Meixide, 1989). The regressions made between the age readings are expected to have a slope of 1 and an intercept of 0, if a systematic difference does not exist. The results of the regressions were:

	Slope	Intercept
Whole otoliths		
Norway-Spain	1.05	0.03
Norway-Portugal	0.81	1.32
Spain-Portugal	0.80	1.03
Sections		
Norway-Spain	1.27	0.24
Norway-Portugal	1.07	1.10
Spain-Portugal	0.82	0.96
Sections - Whole otolith		
Norway	0.96	0.06
Spain	0.80	0.14
Portugal	0.70	0.75

Figure 3.1a presents the mean length at age based on the readings of the otolith sections. Figure 3.1b shows the same plot but adding one year to the Norwegian data. That excercise proved that there was systematically a difference of one year in the readings.

4 NORTHERN STOCK

4.1 Landings in 1988

Estimates of total landings in 1979-1988 from the various fisheries by countries are given in Tables 4.2-4.4 and summarized in Table 4.1.

The catch from directed fishery in Divisions VIIg-k was continued to be recorded as a part of the northern stock.

The total landings from all northern blue whiting fisheries in 1988 were estimated at 522,575 t. This catch was about 17% less than that of 1987. It should be noted that the most remarkable decline of 55% appeared in the Norwegian Sea fishery. The landings from the directed fishery in the spawning area decreased by only 5,5% and from the mixed industrial fishery by 28%.

Since the last landings from the Icelandic mixed industrial trawl fisheries in Division Va were recorded in 1983, the Working Group decided that this table should not be included in the report.

As in the last few years, greater silver smelt was caught in Division VIa as by-catch in the directed fishery. An amount of 11,000 t was recorded and is corrected for in the Norwegian catch statistics.

4.2 Landings in 1989

Preliminary data on the blue whiting catch from January to July 1989, submitted by Working Group members and by some countries, amounted to 396,431 t (Table 4.6).

4.3 Length Composition of Catches

Three countries, USSR, Norway, and the Faroes provided length distributions of commercial catches from the main fisheries in 1988. They were dominated by fish ranging from 26 to 31 cm. Differences between length distributions from the various divisions can be attributed to different time periods during which the fish were taken along their migration routes (Tables 4.6a-e).

For 1988, Norway provided the length compositions from the mixed industrial fishery in Division IVa. The Faroes gave the length composition of by-catches in Division Vb.

For 1989, the length compositions of the catches from the period January-July were submitted by USSR (Table 4.6f).

4.4 Age Composition of Landings

For the directed fisheries in 1988, age compositions were provided by the Faroes, The German Democratic Republic, Norway, and the USSR. These data accounted for 98% of the landings from the directed fisheries. The German Democratic Republic landings from Division Vb were raised to catch in number by age group by the USSR data from the same area and month.

For other landings from the directed fisheries in the spawning area, age compositions of Norwegian landings in the same area and month were used, and catches taken elsewhere were assumed to have the same relative age composition as the total sampled part. The age composition of the catches in the directed fisheries is given in Table 4.7.

For the landings of blue whiting taken in the mixed industrial fisheries in the North Sea (Divisions IVa and IIIa), data were available from Norwegian catches only. These accounted for 55% of the total landings. Landings from other countries in these areas were assumed to have the same age composition as the Norwegian landings in the same months (Table 4.8). By-catches taken by Faroese vessels in Division Vb were raised to catch in number by age group from Faroese samples and are included in Table 4.7. The raised age compositions for the directed fisheries were assumed to give the total age composition of landings (Table 4.9).

4.5 Weight at Age

Mean-weight-at-age data for 1987 were presented by the Faroes, the German Democratic Republic, Norway, and USSR. Landings from other countries were assumed to have the same mean weight-at-age compositions when fished in the same area and period as the sampled catches. Mean weights at age were calculated, weighted by the total landings in numbers in each fishery. The total catch landed in 1988 was compared to the sum of products (SOP) of the total numbers landed in 1988 and mean weight at age. The calculated SOP is virtually the same (within 1%) as the nominal landings. The mean weight at age used in the VPA runs is shown in Table 4.10.

4.6 Stock Estimates

4.6.1 Acoustic surveys in 1989

4.6.1.1 Surveys in the spawning season

During the spawning season of 1989, USSR, Norway, and the Faroes carried out acoustic surveys in the area west of the British Isles and south of the Faroes to assess the size of the blue whiting spawning stock (Isaev and Belikov, 1989; Monstad, 1989).

The Faroes conducted an acoustic survey in April south of the Faroes inside the Faroese fisheries jurisdiction. Only very scarce recordings of mature fish were made.

The USSR survey took place from 25 March-22 April and was conducted northwards from SW of Ireland in the south to the Faroe/Shetland area in the north, i.e., between 50^0N and 62^0N (Figure 4.1). The biomass of blue whiting was estimated at 6.3 million t (or 50.9×10^9 individuals) of which 5.7 million t (or 42.5×10^9 individuals) were estimated to belong to the spawning stock based on the maturity ogive obtained from the cruise samples.

The densest concentrations of blue whiting were found in the southern part of the survey area gradually decreasing further north. The spawning concentrations west of the British Isles were found to have a more westerly distribution than before, and because the survey took place rather late some post-spawning fish might have left the spawning area, resulting in an underestimate of the spawning stock.

The Norwegian survey was conducted from 3 - 24 April and covered approximately the same area as the USSR survey (Figures 4.2. and 4.3). The total blue whiting biomass was estimated at 7.0 million t (or 67.4×10^9 individuals) of which 6.1 million t (representing 58.3×10^9) individuals belonged to the spawning stock.

The densest concentrations, as in the USSR survey, were found in the southern part of the survey area and also at the edge southwest of St. Kilda. The distribution was similar to that of 1988 when for the first time noteable recordings of blue whiting were observed far off the edge, i.e., in the area towards the Rockall Bank. Most of the blue whiting found that far west were spent or running.

The length and age compositions are given in Figure 4.4 for both surveys. The 1986 year class was found to predominate in both the Norwegian and the USSR surveys constituting 32% and 23% respectively of the total number of fish. The main age group has thus shifted from 5 to 3 year olds from 1988 to 1989.

4.6.1.2 Surveys in the feeding season

Four countries carried out acoustic surveys in the Norwegian Sea during the summer of 1989, which, among other objectives, were aimed at determining the blue whiting distribution and abundance. Working notes and information on the results were submitted to the Working Group. The cruise tracks are shown in Figure 4.5. and the area of distribution in Figure 4.6.

From 25 July to 2 August and from 9 to 14 August, a Norwegian research vessel operated in the Norwegian Sea while on its way to and from the capelin grounds in the Jan Mayen area.

Only scattered and very scattered recordings of blue whiting were observed and only few specimens were collected by pelagic trawling. Figure 4.7 shows the length and age composition of the combined trawl catches. The 1986 year class dominated with more than 30% in numbers, whereas the previously strong year class of 1983 only contributed less than 10% of the numbers.

From 27 July to 17 August, the USSR conducted an acoustic survey around and north of the Faroes between 60^0-69^0N and $6^0$30'E-10^0W. Only scattered recordings of blue whiting were observed with a correspondingly low biomass estimate of 600,000 t. The 1983 year class was the most abundant, accounting for more than 22% of the catch in numbers.

The Faroes conducted an acoustic survey north of the Faroes from 7 August - 5 September from 62^0-66^0N between 1^0-13^0W. In most of the surveyed area, except the northwestern part, scattered recordings were made. West of 6^0N, the recordings were almost entirely 0-group blue whiting, 10-17 cm long, with a mean length of 12 cm. East of 6^0W, larger fish of 23-24 cm predominated in the catches but in the southeastern part the older fish were mixed with 0-group fish (Figure 4.8).

An Icelandic research vessel during a scouting survey for Atlanto-Scandian herring in the Norwegian Sea in the first half of June surveyed an area from 69^0-$64^0$30'N between approximately 5^0-$7^0$30'W. No blue whiting was recorded. Similarly, during their annual 0-group fish survey in East Greenland and Icelandic waters in August, which covered the area from 63^0-68^0N and from 10^0W to the East Greenland coast, no blue whiting recordings were identified.

In addition to this, a Norwegian research vessel in the North Sea in July observed blue whiting of length range 27-28 cm in the Norwegian trench area between 61^0 and $57^0$30'N (Aglen, pers. comm.).

4.6.1.3 Discussion

In the period during the acoustic surveys to the west of the British Isles in spring 1989, the weather conditions were excellent enabling the vessels to obtain recordings without acoustic disturbances. The stock was distributed along the Continental Shelf west of the British Isles and it also had a more westerly and southerly distribution compared to the period before 1988.

The two estimates obtained are listed in the text table below (in millions of t) together with the estimates from previous surveys in the spawning area since 1981. The spawning stock is given in brackets.

Year	Estimates
1981	6.1(5.4)
1982	2.5
1983	4.7(4.4), 3.6(3.5)
1984	2.7(2.4), 3.4(2.7), 2.8(2.1), 2.4(2.2)
1985	6.4(1.7), 2.8(2.7)
1986	6.4(5.6), 2.6(2.0)
1987	5.4(5.1), 7.4(6.9), 4.8(4.5)
1988	2.0(1.9), 3.9(3.1), 7.1(6.8)
1989	6.3(5.7), 7.0(6.1)

At the time of the USSR survey, some fish had already spawned and migrated from the slope to the west. These fish were not included in the estimate and, therefore, the result (6.3 million t) might be considered an underestimate.

The Norwegian survey covered more or less the same area at the same time as the USSR survey. The total biomass of 7.0 million t was similar to the biomass estimate obtained in 1988 but the spawning stock biomass was somewhat lower in 1989 than in 1988 due to lower mean weight in the stock.

The two countries' age compositions differ in that the dominant year class, although the same (the 1986 year class) for both surveys was found in greater numbers in the Norwegian catches than in the USSR ones (33% and 23%, respectively). Also in the Norwegian catches, the 1988 year class contributed more than 12% of the total number of fish while it contributed less than 1% to the USSR catches. The previously very strong year class of 1983 was found to have diminished quite drastically in the stock and the main age group has shifted from 5 to 3 year olds since 1988.

The five national surveys carried out during the feeding season in the Norwegian Sea obtained only weak recordings of blue whiting and only the USSR one provided any biomass estimates. The USSR survey did not cover the whole of the distribution area of the blue whiting in the Norwegian Sea and the resulting biomass estimate should, therefore, be considered an underestimate.

The length and age composition of blue whiting in the Norwegian Sea, however, differs between the USSR and the Norwegian observations. The 1986 year class dominated in the Norwegian samples (30% in numbers) as in the spawning area, whereas the 1983 year class was still found to be the dominant year class in the USSR samples.

4.6.2 Catch per unit effort

Data on catch per unit effort from the directed fisheries in 1988 were submitted by the German Democratic Republic, Norway, and the USSR. These countries presented their data broken down by vessel tonnage class, area, and month.

Comparable time series of CPUE data for Divisions IIa, IVa, Vb, VIab, VIIbc, and VIIg-k which could be indicative of stock abundance changes are compiled in Tables 4.11 and 4.12 and Figure 4.9.

In Division IIa, the blue whiting fishery was continued only by the USSR fleet during the whole year. Whereas the total landings and the effort by this country again substantially declined, the catch per hour in 1988 did not show distinct decrease.

In Division Vb, the German Democratic Republic fleet operated only in the second half of the year. There is a constant decline of CPUE since 1985 from 3.58 t/hour to 1.52 t/hour. The USSR CPUE shows a similar declining trend in the January-February period and a sharp decrease by about 50% from 1987 to 1988 during the July/August period.

The data from the spawning fishery, (Divisions VIa,b, VIIb,c and VIIg-k) are variable and do not allow clear conclusions to be drawn as to the stock biomass changes. In some cases, the CPUE declined (Norway, Divisions VIa and VIIb, March/April), whereas in others an increase was observed (USSR, Divisions VIIb,c, February/March).

The Working Group discussed the question of validity of CPUE-data as stock biomass indices. Comparison of catch/hour data (Table 4.12) with catch/day data (Bakanev, 1989) shows until 1985 quite similar trends from 1980. During the period 1986-1988 the catch per hour remains more or less stable, while catch per day after an increase in 1986 declines rapidly in 1987 and 1988 (Figure 4.10.)

The origin of the differences might result from extended time of scouting for suitable concentrations, due to the more scattered distribution.

Due to the uncertanty of the real trend of the biomass changes the Working Group decided to provide catch/day data to allow more detailed analysis of this problem.

4.6.3 Virtual population analysis (VPA)

4.6.3.1 Tuning the VPA to survey results

The Working Group decided to use the tuning module of the ICES VPA program to obtain initial VPA results. The age range chosen for tuning was 3-14 years, and data from 1982-1988 were used. There were four different fleets consisting of USSR and Norwegian acoustic surveys in the spawning area west of the British Isles, combined acoustic surveys in the Norwegian Sea during the feeding season, and CPUE data from USSR commercial fishery in July in the Norwegian Sea.

The data set of the USSR acoustic surveys covered the entire period, while from the Norwegian surveys, data were available for all years except 1982 and 1985. For these two years the data were assumed to be the average of the two neighbouring years. The USSR

CPUE data for July were not available for 1982 and 1987, and for those years, data from August for the USSR and German Democratic Republic trawlers combined were used.

Although the CPUE data, e.g., catch/hour, do not show the same downward trend as the corresponding catch/day data from 1987 onwards (see Section 4.6.2). It was decided to include these data in the tuning. In this way data were included from both the spawning area and the feeding area, and hence this should give better representation of the whole stock.

The results of the tuning are presented in Table 4.14 and in Figure 4.11, the range of the data was limited to cover only the age groups 3-11, even if data vere available up to age 15. The reason is that the resulting Fs for the oldest age groups were very high and variable, also the variance estimates were bad. The resulting VPA run based on the tuning is given in Tables 4.15 and 4.16, the F_{4-8} level of 0.163 was then accepted as an aim for the estimation of the fishing mortalities from a separable VPA run.

4.6.3.2 Estimation of fishing mortality using separable VPA

The initial runs of the separable VPA, including the age groups 0-15+, gave very high residuals for the oldest age groups and for age group 0 in some years. Because of uncertanity in the ageing of the oldest groups it was decided to lower the plus group to 12.

By using the age groups 0-12+, with a terminal F of 0.123 on age 5 and a terminal S of 1.5, the resulting matrix of residuals was acceptable (Table 4.17). The fishing mortalities obtained for 1988 gave an average value of 0.16 for the 4-8 olds, as aimed for (Table 4.18), and the corresponding stock estimates are shown in Table 4.19.

4.6.3.3 Discussion of the stock size estimates

The results of the VPA indicate a spawning stock at 1 January 1988 of 4.4 million t, which is at the same level as 1987 and a sligth decrease from 1986. In the text table below the ranges of the acoustic spawning stock estimates together with the VPA results from 1983-1989 are shown.

	1983	1984	1985	1986	1987	1988	1989
Survey minimum	3.5	2.1	4.1	2.0	4.1	3.1	5.7
maximum	4.4	2.7	"	5.6	5.1	6.8	6.1
VPA	2.6	2.6	3.4	4.5	4.4	4.4	4.5

Biomass in millions of tonnes.

With few exceptions, the spawning stock estimates obtanied from VPA do reflect the acoustic survey results from previous years, but in 1989 the acoustic estimates were higher. The Working Group had confidence in the VPA estimates, and decided to use the figures for prediction of future catch levels.

4.6.3.4 VPA results (Tables 4.18 and 4.19)

The VPA results show that the total biomass has decreased steadily from 1979 to 1982. From 1983 onwards, an increase is again observed, which was an effect of the strong incoming 1982 and 1983 year classes. The spawning stock biomass shows a similar picture, however, the start of the increasing trend began two years later when the strong year classes started to contribute (Figure 4.12B). At the beginning of 1989, the total stock biomass and the spawning stock biomwss were at a level of 6.1 and 4.5 million t respectively.

4.6.3.5 Yield per recruit

Yield per recruit and spawning stock per recruit have been calculated using the data given in Table 4.20 and are shown in Figure 4.12C. The exploitation pattern was obtanied in two steps: First, the smoothed separable fishing mortalities were used as input for an initial prediction with a TAC constraint of 500,000 t (the expected catch in 1989). This gave a reference F of 0.14 for ages 4-8 with a factor of 0.876. Secondly, the exploitation pattern was scaled so that the mean F at ages 4-8 corresponded to the 1989 level. The yield-per-recruit calculations gave a $F_{0.1}$ of 0.22 which is higher than the present level.

The yield-per-recruit calculations on blue whiting are very sensitive to the exploitation pattern on the younger age groups (0-2) due to the high growth rate in the first years.

4.7 Catch Projection and Management Consideration

A projection of catches in 1989 and a resulting total and spawning stock biomass in 1990 were made using the stock size estimate at the beginning of 1989 and the parameters given in Table 4.20. In the projection, a recruitment equal to the 1979-1986 average, excluding the strong year classes of 1982 and 1983 of 11,400 million at age 0, was used for the 1987-1991 year classes. Although a Faroes survey during summer season obtained better recordings of 0-group blue whiting than the last 2-3 years, the average was still used to obtain a recruitment level for the 1989 year class.

It was assumed that the catch in 1989 would be about 500,000 t corresponding to F = 0.14 for ages 4-8 years. The results of the catch projections are given in Figure 4.12D and Tables 4.21 and 4.23.

A continuation of the assumed 1989 F level would result in a catch of 529,000 t, whereas a fishery at the 1988 F level would have resulted in a catch of 70,000 t more.

In Figure 4.13 is given the plot of recruitment versus spawning stock biomass from 1977, when the blue whiting fishery was at full exploitation, to 1986. The estimated F_{med} became 0.13 and is shown in the figure together with F_{high} and F_{low}. Fishing at the F_{med} level would result in a catch of 492,000 t in 1990.

The sparce recordings of blue whiting in the Norwegian sea during feeding season, together with the decline in the landings from the area, could either be caused by a change of the migration pattern or a decrease in the stock size. The increase, however, in the biomass recorded in the spawning area during spring may also reflect a change in the migration pattern, i.e., of a southern component, or a noteable increase of the stock size. The suggestion to separate the northern stock in two main components may help resolve this question in the future.

Except for the 1986 year class, which must be considered above average, there has been no strong year class produced since 1982 and 1983. These two year classes, however, have almost disappeared from the stock, and the 1986 year class has been their successor as the dominant one. This has at least been observed for the spawning stock in 1989, and also to a certain degree in the Norwegian Sea stock in the feeding season. The shift of the main age group from 5-year olds in 1988 to 3-year olds in 1989 may well be a signal of approching a critical level for the stock. The TAC should be held at a low level and it is suggested that it should not exceed the F_{med} level of about 500,000 t in 1990.

5 SOUTHERN STOCK

5.1 Landings

Total landings from the southern area are given in Table 5.1. The Spanish landings had an increase of about 5%, attaining the same level as in 1986. The Portuguese landings, which had been increasing since 1985, decreased in 1988 by about 34%.

5.2 Landings Compositions by Length and by Age

Table 5.2 summarises the length compositions of blue whiting landings from Spanish and Portuguese fisheries in recent years. Length compositions by quarter are presented in Table 5.3.

Data on age composition since 1981 is given in Table 5.4, calculated with age/length keys provided by both countries. As it can be observed, most of the fishing was based on the first five age groups, mainly on the 1-, 2-, and 3-year groups.

Qualitative data on discards are not available, but it is assumed they are considerable. Consequently, data on the real catch composition are not provided.

5.3 Weight-at-age and SOP Check

Weight-at-age data from both fisheries, the Spanish and the Portuguese, are presented in Table 5.5. The total landings from 1988 was compared to the sum of products (SOP) of the total numbers landed in the same year, and to the mean weight at age. The SOP calculated was within about 3% of nominal landings (Table 5.4).

5.4 CPUE Data

Definition of a representative effort unit is difficult, due to the lack of information on discards from the Spanish and the Portuguese fisheries. However, information on CPUE data is given.

In the case of Portugal, no directed fishery exists; blue whiting is caught almost exclusively by bottom trawlers, and so, fishing hours estimated for this fishery (Cardador, pers. comm., 1989) were adopted (Table 5.6b).

In Spain, apart from the single bottom trawl fishery there is a pair-trawl fishery that usually does not discard blue whiting. So, CPUE from this fishery gives a more correct index of abundance. Data on catch per unit effort from both fisheries are presented all together in Table 5.6a and split by fleet in Table 5.7.

5.5 Maturity at Age

Maturity at age was assumed to be the same as used in last year's assessment (Table 5.16).

5.6 Tuning of Virtual Population Analysis

The tuning method was applied to provide a preliminary estimate of terminal F values. It was decided to use CPUE data from the pair-trawling fleet (Spanish fishery) due to the fact that discards are almost non-existant for these vessels. Catch data from Spanish surveys were also included (Tables 5.8. and 5.9). No survey was done in 1987, so the average of the years 1986 and 1988, for the same year classes was assumed.

The output of the tuning is shown in Table 5.10 and it can be observed that the variance ratio is not high for most ages. The log catchabilities of the tuning results have been plotted and are presented in Figure 5.1.

5.7 Separable Virtual Population Analysis

Mean fishing mortality for ages 1 to 4 obtained through the VPA tuning (Table 5.11) was 0.49. This fishing mortality level was used as terminal F, at age 2, to run a separable VPA with terminal S of 1.5. The matrix of residuals is shown in Table 5.12. It can be observed that the residuals are not high, and the selection pattern derived is similar to that from the tuning analysis (Figure 5.2).

5.8 VPA Results

Tables 5.13 and 5.14 and Figures 5.3A and B show the final fishing mortalities and stock size estimates based on the separable VPA results. In 1988, the spawning stock biomass attained the same level as in 1982 (39,000 t) and the lowest level was in 1984 (31,000 t).

5.9 Recruitment VPA Calibration

Numbers at age 0 estimated by final VPA were regressed against the 0-group indices from Spanish bottom trawl surveys carried out in September/October from 1981 to 1988. CPUE data at age 1 were taken as indices of recruitment of previous years. The recommended program for this was run. Table 5.15 shows predicted values for 1987 and 1988 year classes. These new calculated values were used to obtain numbers for the 1987-1988 year classes in 1989 for the input of the prediction and the yield per recruit calculations.

5.10 Yield-per-Recruit and Catch Forecast

Terminal populations from the final VPA (corrected for ages 1 and 2) and separable fishing mortalities were used for the catch forecast (Table 5.16). An average recruitment at 1,100 millions at age 0 from 1984-1988 was assumed for the years 1989-1991.

Results of the yield per recruit are shown in Figure 5.3C. In Tables 5.17 and 5.19, two options of catch forecast are presented. In option 1, a level of catch similar to that of 1986-1988 was fixed for 1989 assuming status quo F. Even with a fishing mortality in 1990 at the level of F_{high} the spawning stock stays at the level of 33,000 t. Detailed results for this option are shown in Table 5.18. In option 2, a catch at the level of TAC established by the European Community was fixed for 1989. In this case, with a fishing mortality in 1990 at the level of F_{high}, the spawning stock will reach the lowest level of the last years.

5.11 Biological Safe Limits

F_{med} and F_{high} are shown in Figure 5.4; these were obtained by plotting spawning stock biomass against recruitment for the period 1981-1987. No evidence of any stock/recruitment relationship could be observed (Figure 5.4). The level of SSB has varied little in the period.

5.12 Management Considerations

Uncertanties concerning stock identity, distribution of the spawning stock and the fact that the southern fishery is mainly based on the first five age groups, indicate the need to maintain the juvenile fishery at a controlled level.

Acoustic surveys in the southern area are needed to investigate distribution and stock size. A coordinated Spanish-Portuguese acoustic survey in March/April 1988 was carried out for pelagic species, covering all the Atlantic-Iberian coast with the exception of the southern coast of Spain. In the Portuguese area the blue whiting distribution was not fully observed because the survey only covered the sardine distribution area. Also, spatial distribution off the Spanish coast is only known down to the 500 meters isobath, as can be seen in Figure 5.5. Thus, part of the distribution area is still not known (ICES, Doc. C.M.1989/ H:G).

6 ZONAL DISTRIBUTION

The four hydroacoustic surveys which took place in the Norwegian Sea during the summer of 1989 and the one in the North Sea, have not resulted in any reliable estimate of the total stock size. The surveys' cruise tracks and the overall geographical distribution of blue whiting are shown in Figures 4.5 and 4.6, respectively. Acoustic survey data collected during the summer period of 1989 suggested that only an insignificant part of the total stock might migrate to the feeding area. This is also supported by survey results from a few recent years as well as by the decreasing trend in the landings, especially from the Norwegian and the Faroes zones (Table 4.1).

Spawning blue whiting aggregate in the area west of the British Isles to spawn in March-April. Since 1980, acoustic surveys have been carried out in that area in order to estimate the biomass of the spawning stock. The results of the various surveys were not very consistent in the beginning, but the agreement be-tween the surveys has been improving considerably in later years. In the spring surveys, however, the biomass estimates are not divided into national zones. The Working Group has attempted to do this from distribution maps presented in the Working Group reports from 1981 to 1989 (Table 6.1).

This could not, however, be done for all surveys as the surveys were carried out at different times and did not cover the same areas. The results obtained are only estimates and should be interpreted with caution.

Since 1986, surveys in the Norwegian Sea during the feeding period have only been conducted on a national basis. No reliable biomass estimates for the whole stock in that area have been obtained, and the Working Group feels unable to provide any reliable quantitative distribution within national economic zones from the results.

The total landings of blue whiting from 1978 to 1988 are updated and divided into national fisheries zones in Table 6.2. The table was derived from data brought to the meeting by the Working Group members, and official statistics reported to ICES. For some countries the landings were split according to a statistic based on the current reporting of the fleet. For other countries, the most appropriate assumptions were made from the statistics.

The fishery zone of Jan Mayen was not declared until 1981, and an unknown part of the catches allocated to international waters in the years prior to 1981 was actually taken in the Jan Mayen zone.

7 DISTRIBUTION IN TIME AND SPACE OF THE BLUE WHITING STOCK

In the 1985 report of the Blue Whiting Assessment Working Group (Anon., 1986), available knowledge from various sources on the spatial and temporal distribution of the blue whiting stock at different stages of its life was summarized. The general conclusions together with any new information and ideas on this subject are presented in this section.

Spawning area

The main spawning areas of the blue whiting extend from west of Ireland northwards along the continental slope west of the British Isles and along the slope of the Rockall Bank. The distribution pattern of the blue whiting spawning stock has been gradually changing in recent years. The spawning has been observed further offshore and the centre of gravity of the spawning aggregations has progressively been shifting southwards to the area of the Porcupine Bank (Monstad,a,b, 1989, Isaev and Belikov, 1989).

Furthermore, there is some evidence suggesting that the northern stock of blue whiting may be separated (morphometrically, biologically and geographically) into two distinct populations, one with the main spawning area north of latitude 56^{0}N, and the other with the main spawning area south of 56^{0}N (see Section 2). If this is so, the observed shifting of the centre of gravity of the spawning towards the Porcupine Bank area may be a reflection of changing population dynamics of the two spawning populations. Nevertheless, it can be concluded that the main bulk of the northern blue whiting stock spawns in March-April to the west of the British Isles inside the fisheries jurisdiction of the EC.

Nursery area

No additional information is available on the planktonic drift of blue whiting eggs and larvae to that given in the report of the Working Group in 1986 (Anon., 1986). In that same report the present knowledge on the distribution of the juveniles was summarized. The only conclusive additional information to that is from a Faroese survey conducted around and north of the Faroes and in the Faroe-Iceland Ridge area in August-September 1989. Noteable recordings of 0-group blue whiting (10-17 cm long) were made, especially on the ridge between the Faroes and Iceland.

Postspawning and prespawning distribution

Since 1986, when the international acoustic surveys coordinated by ICES ceased, surveys in the Norwegian Sea have been conducted on a national basis and the results have been brought to the Working Group meetings for discussion. This has been done ever since, but the Working Group feels that no reliable estimate on the total stock size or its quantitative distribution in the area could be given from the results. The overall geographic distribution in the Norwegian Sea in summer 1989, however, is presented in Figure 4.6.

It is clear, however, that considerable changes have taken place in the migration pattern of the blue whiting into the Norwegian Sea in recent years (Shevenko, Isaev and Belikov, 1989; Monstad 1989). In 1978-1981, the feeding migrations covered a large area, including the northern and northwestern areas. From 1982 and onwards, the feeding area has contracted markedly and the blue whiting has virtually stopped migrating north of 65^0-66^{0}N in any great numbers.

The reason for the changed migration pattern of the feeding stock is thought to be caused by large fluctuations in the stock size and the age composition of the stock, resulting from the fisheries and changes in the recruitment.

8 RECOMMENDATIONS

1) The Working Group considers it very important that the northern blue whiting stock is monitored each year. The surveys of the spawning stock during the spring have proved to be very valuable and the Working Group recommends that they be continued.

2) Because of the evidence of some changes in the stock distribution and in the light of new results of stock separation, the Working Group stresses the importance of surveys and recommends that surveys be done to investigate the distribution in the southern and southwestern area.

3) Taking into account new suggestions on the northern stock separation, the Working Group recommends that further investigations be undertaken to have this important question clarified.

4) The Working Group recommends, that the countries involved in directed blue whiting fishery provide their historical CPUE data for the next meeting in terms of catch/day from 1980 onwards, and as catch/day as well as catch/hour in 1990.

5) Although it is difficult at present to indicate the precision of the stock estimates obtained by the acoustic surveys in the Norwegian Sea, the results from the 1981-1988 surveys have given appreciable information, especially about the younger year classes. The Working Group, therefore, recommends that the acoustic surveys during the summer/autumn season of 1990 should be carried out on a national basis, and the results brought to the Working Group.

6) The Working Group recommends that further investigations should be carried out on selectivity with the mesh sizes still in use, and other mesh sizes both in the mixed industrial and in the directed fishery.

7) It is recommended that for future analysis of stock size, the age range 0-12+ years should be used. Historical data should be compiled in accordance with this for future meetings.

8) A workshop for ageing Blue whiting otoliths is recommended to be held in 1990 in Spain. The Working Group proposes Mr M. Meixide as coordinator.

Table 5.16

List of input variables for the ICES prediction program.

BLUE WHITING SOUTERN STOCK
The reference F is the mean F for the age group range from 1 to 4

The number of recruits per year is as follows:

Year	Recruitment
1989	1100.0
1990	1100.0
1991	1100.0

Proportion of F (fishing mortality) effective before spawning: .2500
Proportion of M (natural mortality) effective before spawning: .2500

Data are printed in the following units:

Number of fish:	millions
Weight by age group in the catch:	kilogram
Weight by age group in the stock:	kilogram
Stock biomass:	thousand tonnes
Catch weight:	thousand tonnes

age	stock size	fishing pattern	natural mortality	maturity ogive	weight in the catch	weight in the stock

Table 5.17 Option 1.

Effects of different levels of fishing mortality on
catch, stock biomass and spawning stock biomass.

BLUE WHITING SOUTERN STOCK

Year 1989					Year 1990					Year 1991	
fac-tor	ref. F	stock biomass	sp.stock biomass	catch	fac-tor	ref. F	stock biomass	sp.stock biomass	catch	stock biomass	sp.stock biomass
1.0	.50	141	43	33	$F_{0.1}$ .3	.13	140	50	10	164	70
					F_{88} 1.0	.50		45	35	139	45
					F_{med} 1.3	.68		43	43	129	38
					F_{high} 1.6	.80		42	49	124	33

The data unit of the biomass and the catch is 1000 tonnes.
The spawning stock biomass is given for the time of spawning.
The spawning stock biomass for 1991 has been calculated with the same fishing mortality as for 1990.
The reference F is the mean F for the age group range from 1 to 4

Table 5.19 Option 2.

Effects of different levels of fishing mortality on
catch, stock biomass and spawning stock biomass.

BLUE WHITING SOUTERN STOCK

Year 1989					Year 1990					Year 1991	
factor	ref. F	stock biomass	sp.stock biomass	catch	factor	ref. F	stock biomass	sp.stock biomass	catch	stock biomass	sp.stock biomass
1.7	.88	141	39	TAC 50	$F_{0.1}$ 1.3	.13	123	38	8	149	57
					F_{88} 1.0	.50		34	27	129	38
					F_{med} 1.3	.68		33	34	121	32
					F_{high} 1.6	.80		31	39	117	28

The data unit of the biomass and the catch is 1000 tonnes.
The spawning stock biomass is given for the time of spawning.
The spawning stock biomass for 1991 has been calculated with the same fishing mortality as for 1990.
The reference F is the mean F for the age group range from 1 to 4

Table 6.1 Acoustic estimates from various surveys in the spawning season divided on areas (%) within and beyond areas of national economic zones of NEAFC member countries.

Year	International	Faroes	Norway	EEC	Surveys

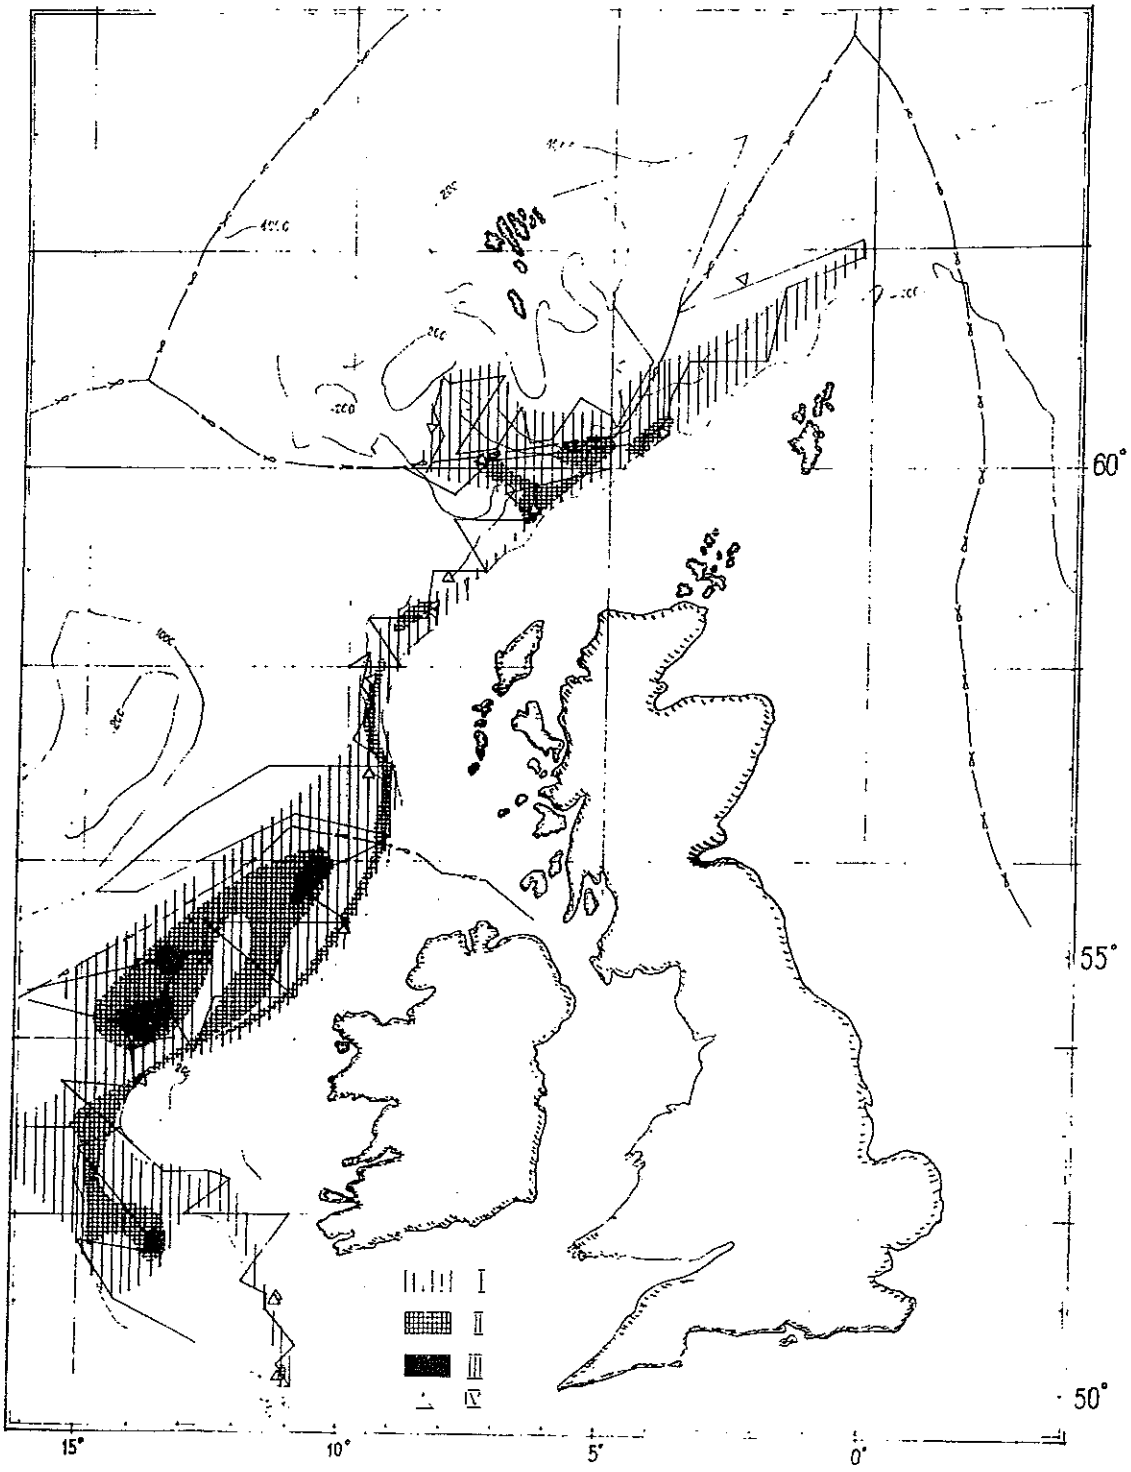

Figure 4.1 Distribution of BLUE WHITING biomass in the period from 25 March to 22 April 1989 (USSR Survey):

1. <150 t/sq. mile;
2. 151-500 t/sq. mile;
3. >500 t/sq. mile;
4. trawlings.

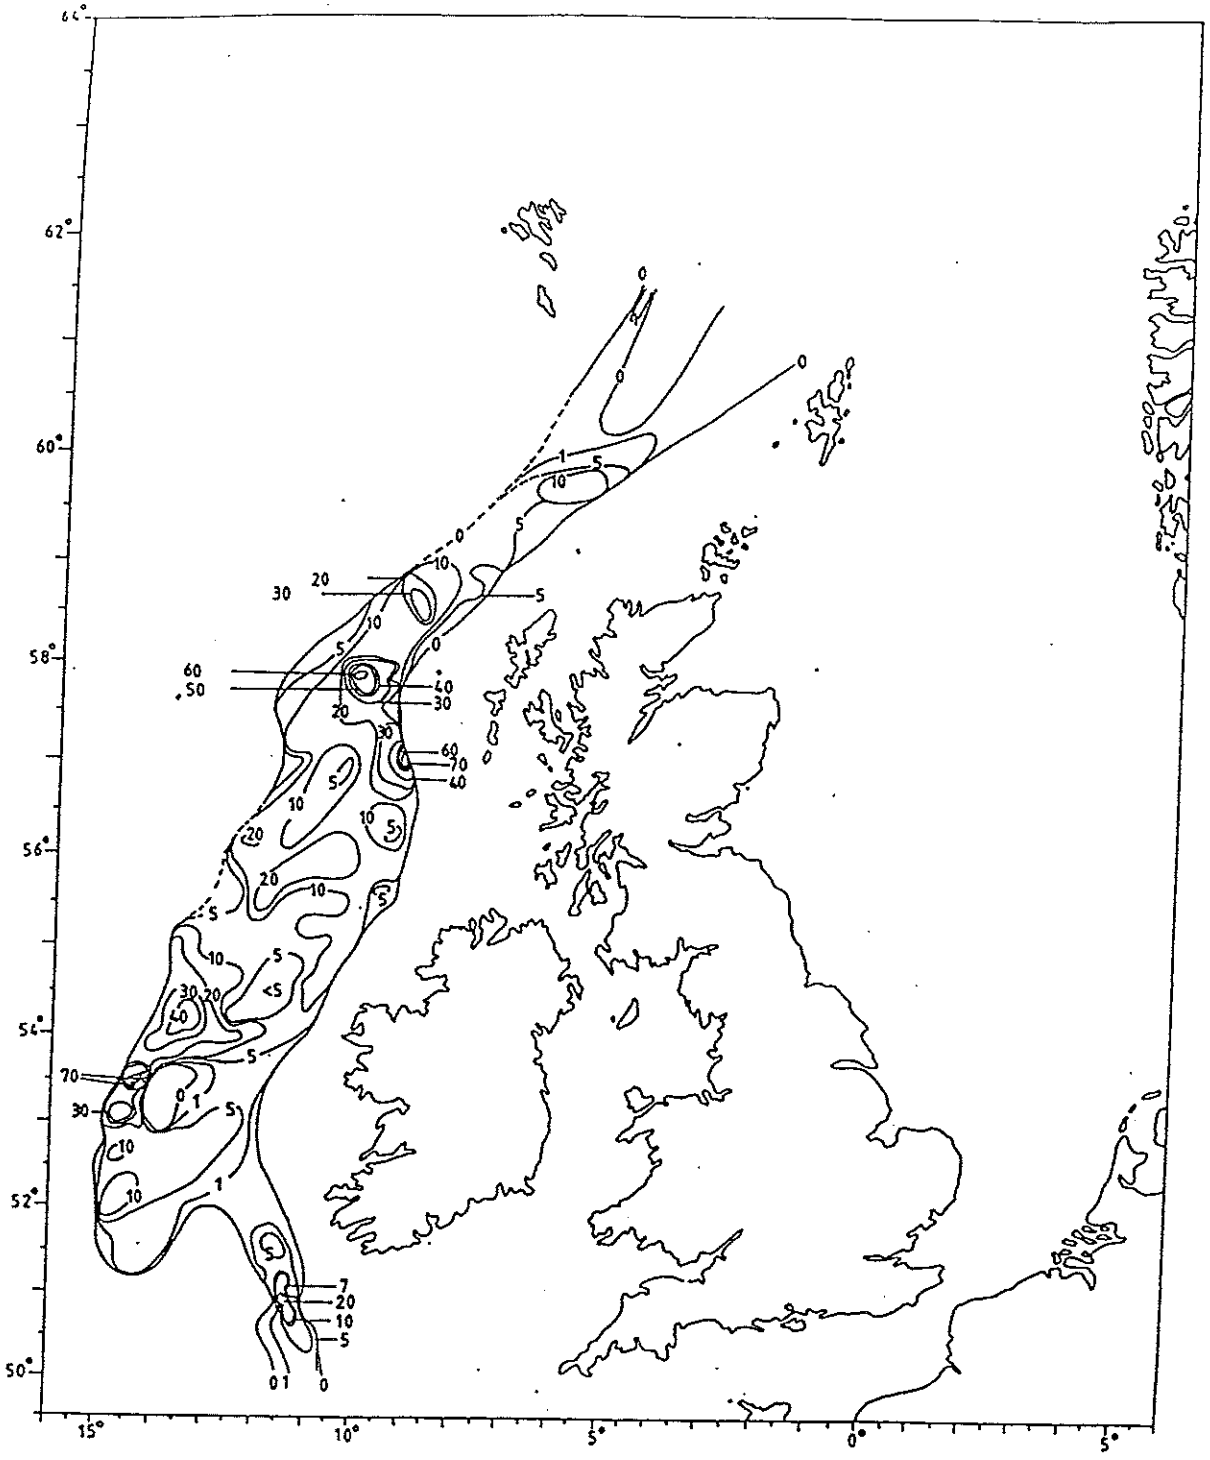

Figure 4.2 Distribution and densities of BLUE WHITING in April 1989 (Norwegian Survey). Echo intensity in $m^2/n.mile^2 \times 10^{-2}$.

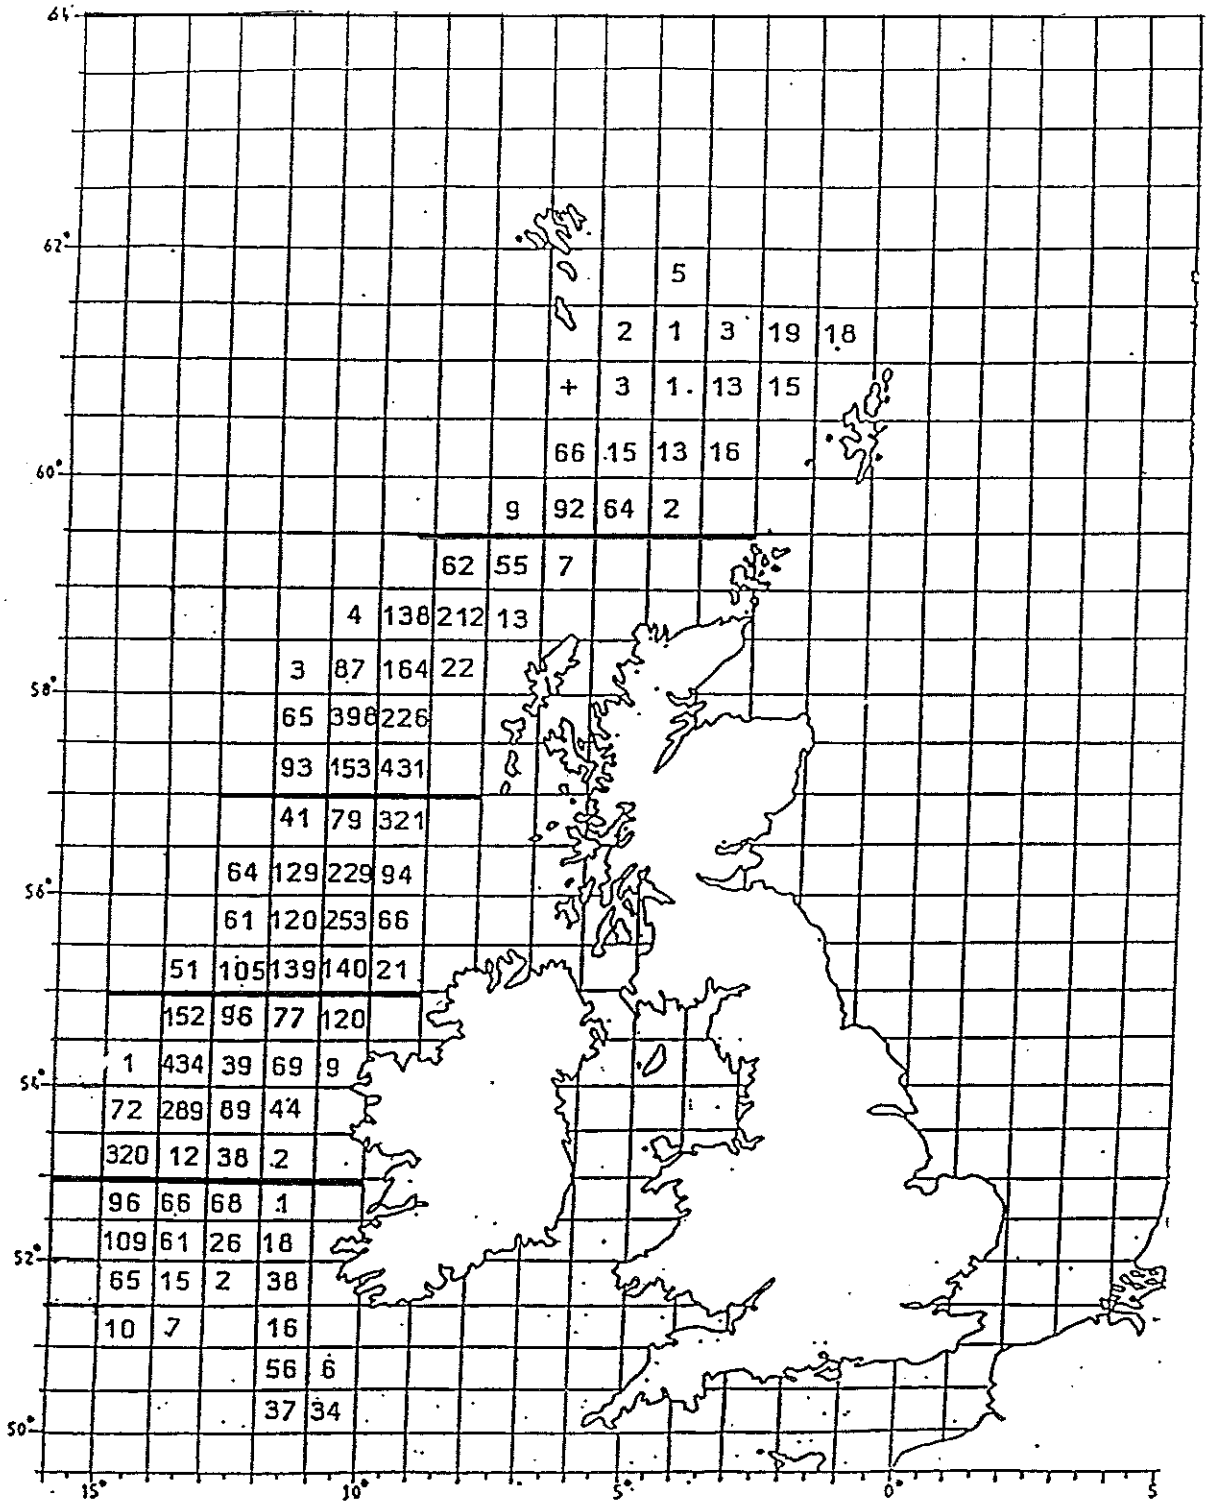

Figure 4.3 Biomass of BLUE WHITING (1,000 t) by rectangles in April 1989.

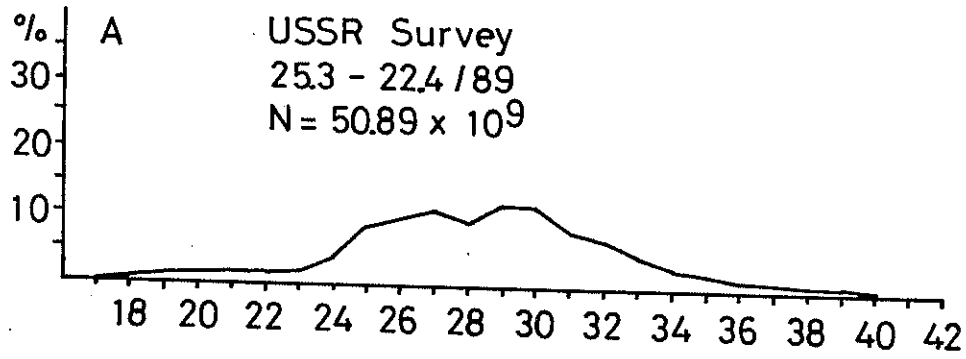

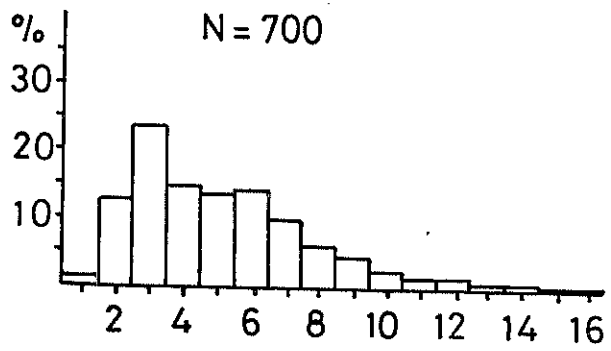

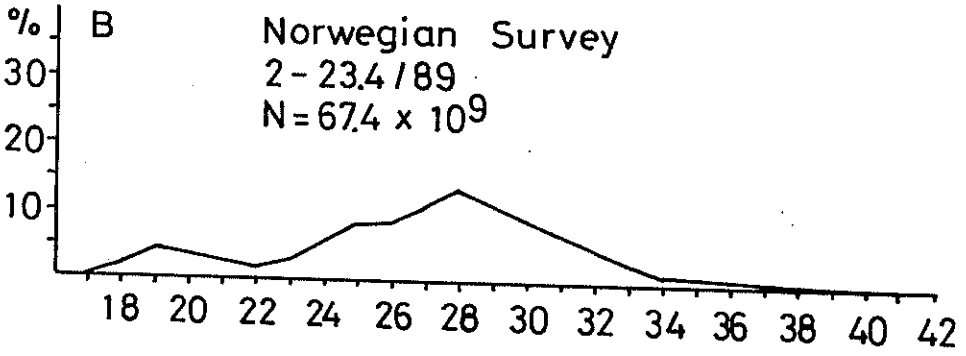

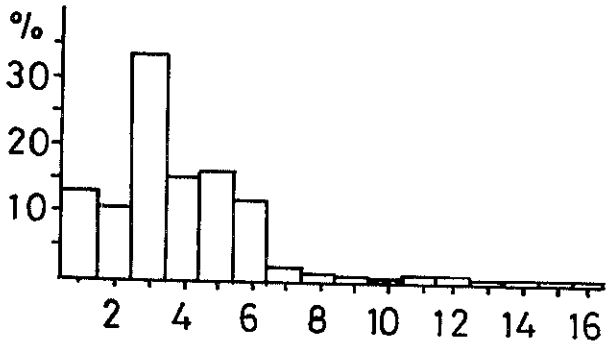

Figure 4.4 Total length and age composition (%) of BLUE WHITING from the area west of the British Isles during spring of 1989.

The length distribution and the age distribution of Norway are weighted by abundance N.
The USSR age distributions are based on number of aged fish.
